Abstract

Multidrug-resistant tuberculosis is an increasing public health concern in many parts of the world, especially in low-income countries, where most cases occur. Traditional drug susceptibility testing is either time-consuming, such as the proportion method on solid media, or expensive, such as the BACTEC 960 System. The aim of this study was to evaluate a nitrate reductase assay (NRA) using sodium nitrate (NaNO₃) on smear-positive sputum for the detection of multidrug-resistant *Mycobacterium tuberculosis* (MDR-TB) and compared it with the nitrate reductase assay using potassium nitrate (KNO₃) and Proportion Method (PM) or Direct Proportion Method (DPM). The NRA-NaNO₃ results were compared with other methods for 91 sputum samples for which comparable results were available. The sensitivity (ability to detect true drug resistance) and specificity (ability to detect true drug susceptibility) of the NRA-NaNO₃, were 100% and 96%, 93% and 100%, 85% and 98%, and 76% and 97% for Rifampin, Isoniazid, Streptomycin and Ethambutol, respectively. The results were in most cases available in 10 days. NRA-NaNO₃ is simple to perform and provides a rapid, accurate, especially in low-income countries and might become alternative to traditional methods.

1. Introduction

Tuberculosis (TB) remains one of the major causes of morbidity and mortality from infection in humans. The World Health Organization (WHO) estimates that one third of the world population is infected with *Mycobacterium tuberculosis*, 9.4 million new cases of tuberculosis and 1.3 million deaths from tuberculosis occurring worldwide. The worldwide incidence is 140 cases per 100,000 population (WHO, 2010).

The emergence of multidrug-resistant (MDR) tuberculosis, defined as tuberculosis caused by strains resistant to the two first-line drugs (Isoniazid and Rifampin), and extensively drug-resistant (XDR) tuberculosis, defined as tuberculosis caused by strains resistant to the two above mentioned drugs, at least one fluoroquinolone, and at least one of three injectable second-line drugs (Amikacin, Kanamycin and Capreomycin) (Bwanga et al., 2009).

Data from more than 100 countries collected during the last decade show that 5% of all TB cases have MDR-TB. There were an estimated 500,000 new MDR-TB cases in 2007. Twenty-seven countries accounted for 85% of all MDR-TB cases. The top five countries with the largest number of MDR-TB cases are India, China, the Russian Federation, South Africa and Bangladesh, while XDR-TB has been found only in 58 countries to date (WHO, 2010).

Tuberculosis is one of the most important health problems worldwide. For this reason, the rapid diagnosis of TB drug resistance is a priority to avoid the spread of resistant strains (Palomino, 2005). There are different methods for detection of TB drug-resistance. The BACTEC radiometric system has the advantage of being more rapid (5-10 days), but requires the use of radio-isotopes and can be costly to be performed routinely. Commercial tests (MGIT, E-Test) and molecular tools (INNO-LIPA) have been proposed, but are expensive and also impractical for routine use (Lemus et al., 2004; Palomino, 2005).

For developing countries, it would be useful to have a simple and inexpensive test that could rapidly detect drug-resistant *M. tuberculosis* strains. Several methods have been reported, including colorimetric methods that use redox indicators (MTT and resazurin) and phage amplification technology (Martin et al., 2003; Simboli et al., 2005).

Conventional tests for the detection of drug resistance require several weeks to yield results. Recently, alternative rapid methods have been developed (Solis et al., 2010). Among them, the colorimetric nitrate reductase assays (NRA), based on the ability of *M. tuberculosis* to reduce nitrate to nitrite,
has been successfully applied on solid medium. This indirect method result in less than 14 days but requires an initial 3 to 4 weeks for cultivation of the isolate (Coban et al., 2004). Another conventional method is proportion method (PM) or Direct Proportion Method (DST) for mycobacterial drug susceptibility testing requires several weeks of incubation to give results (Canetti et al., 1989).

The aim of the present study was to comprise performance of a direct NRA, PM and using sodium nitrate (NaNO₃) with clinical sputum samples instead of bacterial isolates in determining the susceptibilities to rifampin (RIF), isoniazid (INH), streptomycin (STR), and ethambutol (EMB) of M. tuberculosis strains in microscopy-positive clinical samples from patients with pulmonary tuberculosis.

2. Materials and Methods

2.1. Specimen Processing

From February to August 2012, a total of 100 smear-positive sputum samples from new and treated patients, with positive score of 1 or more (>1 acid-fast bacillus-AFB) per field (WHO, 1998), were collected at the tuberculosis chest disease clinic in Basrah city. The samples (one per patient) were processed using the Modified Petroff Digestion Decontamination (WHO, 1999). The sediment was re-suspended in 1ml of sterile distilled water, and portions were plated onto NRA drug susceptibility testing medium and into a Lowenstein Jensen (LJ) tube without nitrate, which was later used for the Indirect Proportion Method (IPM)

2.2. Direct NRA Drug Susceptibility test (by using NaNO₃)

The NRA was performed as described previously by Musa et al.(2005). We used standard LJ medium with 1,000 µg of KNO₃/ml and with or without Rifampin (RIF). For LJ medium with RIF, the critical concentration of 40µg/ml was used. Before NRA, part of the decontaminated suspension was diluted 1:10 in sterile distilled water, and portions were plated onto NRA drug susceptibility testing medium and into a Lowenstein Jensen (LJ) tube without nitrate, which was later used for the Indirect Proportion Method (IPM)

2.3. Direct Proportion Method (DST) or Proportion Method (PM)

The technique was carried out on normal LJ medium according to the laboratory standard procedure (Canetti, 1993). The medium was prepared in 7-ml portions in 150-by-155 mm glass tubes with rubber plugs, with or without antimicrobial agents incorporated. Critical concentrations of antituberculosis drugs were the same as were used for NRA. The critical proportion values were 10% for RIF and STR and 1% for INH and EMB. For each strain, part of the suspension was diluted 1:100, and 0.2ml of the dilution was inoculated into two tubes of LJ medium without antibiotics. Then, 0.2ml of the undiluted suspension was inoculated into the tubes containing LJ medium with antibiotics. The tubes were incubated at 37ºC. Final susceptibility results were reported after 40 days following the laboratory standard procedure, but preliminary results could be reported earlier for resistant strains, sometimes as early as after 20 days.

2.4. Direct NRA by using Sodium Nitrate (NaNO₃)

The method is similar of direct NRA drug susceptibility test but using sodium nitrate (NaNO₃) in replacement of potassium nitrate (KNO₃) (Maira et al., 2012).

2.5. Quality

Internal quality control was done using the fully susceptible M. tuberculosis H37Rv and known MDR M. tuberculosis isolate.

2.6. Statistical Analysis

In the present study, the term sensitivity reflects the ability to detect a true drug resistance in a strain, whereas specificity reflects the ability to detect a true drug susceptibility. Statistical analysis of data was carried out by using SPSS analysis (Moore, 2000).

3. Results

One hundred sputum samples of M. tuberculosis were analyzed by the Direct NRA-KNO₃, Direct NRA-NaNO₃ and DST methods. Table 1 shows the results obtained with Direct NRA-KNO₃ compared to DST method using sputum samples. The smear results for AFB were positive with more than 10 AFB per field (+++). Of the 100 smear microscopy-positive results, 9 had negative growth control as determined by the NRA method and could thus not be used in the comparison. Then, 91 sputum samples could be used for the comparison between three methods.

In table 1, for RIF, 60 isolates were found resistant and 24 susceptible by both methods. For INH, 64 isolates were resistant and 22 susceptible by both methods; four strain gave a discordant result being susceptible by DST method. For STR, 67 isolates were resistant and 20 susceptible by both methods; three isolates were susceptible by DST but resistant by NRA-KNO₃. In other hand, for EMB, 67 isolates were
resistant and 18 susceptible by both methods; 4 isolates were susceptible by DST but 2 isolates susceptible by NRA-KNO₃. The results were available in 10 days for 11 samples, in 14 days for 45 samples, and in 18 days for 35 samples.

Table 2 shows the sensitivity and specificity obtained with NRA using NaNO₃ and KNO₃ compared to the DST method. Drug susceptibility testing for RIF showed a sensitivity of 93% with KNO₃ and 100% with NaNO₃, but specificity was 96% for both nitrate sources. For INH the sensitivity was 90% with KNO₃ and 93% with NaNO₃ while the specificity was 97% and 100%. For STR the sensitivity was 80% with KNO₃ and 85% with NaNO₃ while the specificity was 94% and 98%. In addition, for EMB the sensitivity was 71% with KNO₃ and 76% with NaNO₃ while the specificity was 90% and 97%.

Figure 1 shows the comparison of three methods are NRA- NaNO₃, NRA-KNO₃ and DST.

4. Discussion

To our knowledge, this is the first evaluation of the direct NRA in Iraq. The most worrisome trend during recent years is an increase in multidrug-resistant MDR (for example resistant to RIF and INH) TB strains. Rapid detection of MDR strains is very important to restrict their spread in the population. Current method for DST of MDR-TB are either costly or very slow. So, a cost-effective and rapid drug-susceptibility method is required to guide the treatment of TB (Coban et al., 2004; Mishra et al., 2009). Complete agreement between the results of the direct NRA and DST method was found for RIF, which is important since RIF, together with INH, is the most important antituberculosis drug. Resistance to RIF is also almost always associated with multidrug resistance (Vareldzis et al., 1994) and can thus serve as a marker of MDR of $M. tuberculosis$ strains if resources are limited.

The direct NRA was comparable to the direct DST method regarding susceptibility testing of INH (sensitivity to detect resistant was 90% with specificity was 97%). In addition, the sensitivity to detect resistance to STR and EMB were low to be acceptable (80% and 71%), but the specificity were 94% and 90% respectively. Results for RIF and INH susceptibility were similar to indirect NRA method (Sethi et al., 2004; Musa et al., 2005). These results may be need to adjusting the critical drug concentrations used in the NRA test, although the susceptibility of $M. tuberculosis$ to STR and EMB is more complicated to determine the antibiotic sensitivity (Maira et al., 2012).

The NRA method utilizes the detection of nitrate reduction as an indication of growth, and therefore, results can be obtained faster than by visual detection of colonies. The ability to reduce nitrate is typical for $M. tuberculosis$, although some other mycobacterial species, like Mycobacterium kansasii, and most rapid growers share this characteristic, nitrate reductase-negative strains of $M. tuberculosis$ are rare (<1%)(Rosales et al., 2009).

In the other hand, this study showed that the NRA gave similar results using KNO$_3$ or NaNO$_3$ as nitrate source. NRA using NaNO$_3$ showed high sensitivity and specificity for RIF (100% and 96%) and INH (93% and 100%). These results are in agreement with previous studies presented in a meta-analysis that evaluated the accuracy of the NRA for the detection of MDR.

According to that meta-analysis; the sensitivity and specificity were more than 94% and 92% for RIF and INH (Maire et al., 2012). Another important finding in this study was that 97% of the isolates showed results in 10 days with NRA using NaNO$_3$, whereas 88% of the isolates gave results in 10 days with NRA using KNO$_3$ in the previous studies (Coban et al., 2004). Our study suggests the use of NaNO$_3$ as the source of nitrate for NRA.
