Abstract

Olive is the most widely grown fruit tree in Jordan; it is annually attacked by the olive fruit fly, *Bactrocera oleae* (Rossi), whose larvae usually cause great economic losses in fruit yield. *Alternaria solani*, *Aspergillus niger*, *Cladosporium herbarum*, *Fusarium solani*, *Penicillium digitatum*, *P. italicum* and *Rhizopus stolonifer* were found associated with the fly infestation with a sample frequency ranging from 6.7-33.3%. *Penicillium digitatum* was the most dominant species. All molds were vulnerable for a hot water treatment at 50 and 70ºC as indicated by their low spore germination and colony-forming unit except for *P. digitatum* and *P. italicum* which were the most heat-tolerant. When the olive oil was inoculated with pure cultures of these molds, the mold fungi were able to colonize olive oil. *Rhizopus stolonifer* was the greatest colonizer and besides *Alternaria solani*, both had obviously reduced the oil peroxide value over the control without greatly affecting the oil free fatty acid content.

Keywords: *Bactrocera oleae*, Jordan, *Olea europea* L., Olive fruits, Spore germination.

1. Introduction

Olive, *Olea europea* L., is the most widely grown fruit tree in Jordan occupying about 77% of the total area planted with fruit trees and 34% of the whole planting area covering now more than 130 thousand hectares (Anonymous, 2013). Olive plantation is a traditional part of the Jordanian agriculture (Al-Shdiefat *et al*., 2006; 2009) having a social, economic and environmental importance; it occupies the same position in the surrounding Mediterranean Basin countries (Loumou and Giourga, 2003).

Olive fruits are a valuable commodity worldwide; they are consumed as whole, as a table olive that is stuffed and sliced and as olive oil produced by milling fruits that must be prepared using safe conditions based on international olive oil standardization (Tokuşoğlu *et al*., 2012).

Contamination of the fruits by hazardous microorganisms may occur through insect pest infestation, when they fall on the ground or by workers during handling (Asehraou *et al*., 1992; Chliyeh *et al*., 2014). One of the most important insect pests that usually attack olive in Jordan is olive fruit fly (*Bactrocera oleae* (Rossi) formerly *Dacus oleae* (Diptera: Tephritidae)) whose larvae usually cause great annual economic losses in fruit yield through making fruit tunnels and enhancing the infection of fungal molds (Al-Raddad and Mustafa, 2008).

Mycotoxins are secondary metabolites produced by microfungi that are capable of causing disease and death in humans and other animals (Bennett and Klich, 2003). Many types of mycotoxins are produced by mold fungi including aflatoxin, citrinin, alkaloids, fumonisins, ochratoxin A, patulin, trichothecenes, and zearalenone (Abarca *et al*., 2003; Abrunhosa *et al*., 2002; Bennett and Klich, 2003). Mycotoxins could act as nephrotoxic teratogenic, immunotoxic, genotoxic, mutagenic and carcinogenic agents and cause other human health hazards, all of which lead to life-threatening diseases (Creppy *et al*., 1985; El Adlouni *et al*., 2000; Bhat *et al*., 1997).

Some olive mills usually use hot water to wash olive fruits before processing, which may drastically raise milling temperature. The milling temperature is kept under 27°C which is crucial to olive oil quality. Sometimes, hot water is added to olive paste during oil extraction for increasing the oil release from the tissues especially from olive fruits yielded under rainfed and non-supplementary irrigation conditions. If the temperature exceeds 27°C, the more volatile aromas are lost and oil oxidation rate is increased, thus reducing oil quality. The chemical content of polyphenols, antioxidants, and vitamins of the oil is also reduced by higher temperatures...
their influence on some oil quality parameters.

Therefore, the present study was conducted to isolate and identify the various mold fungi that are usually associated with olive fruit decay, to evaluate their ability of resisting hot temperature and colonizing olive oil and their influence on some oil quality parameters.

2. Material and Method

2.1. Mold Isolation, Culture and Identification

About 200 fully-mature and ripped olive fruits, previously infested with olive fruit fly, showing internally mold growth, were collected during Nov. 2014 from some trees belonging to some olive cultivars; Nabali, Nassohi, Rassei and Nabali Mohassan grown at the Agricultural Research Station (31° 16' N, 35° 45' E and ca 920 meters above sea level) of Faculty of Agriculture, Mutah University, Karak, Jordan. The part of olive fruit sample, showing the mold growth (0.5cm-in-diameter piece), was cut off and transferred into potato dextrose agar medium-containing Petri dish, 3 pieces of the same fruit/plate (Asehraou et al., 1992). All culture dishes were then incubated at 25°C in a growth chamber for one week. A week later, all fungal colonies growing out from the pieces were identified under 100 and 400X slide stereoscopic microscope.

2.2. Mold Type Frequency

The percentage of each identified mold species was determined by counting the number of fruits showing positive isolation per fungal species divided by the total number of collected samples and multiplied by 100%.

2.3. Influence of Hot Water on Mold Spore Germination

To estimate the influence of hot water treatments at different temperatures on mold growth and development indicated by Colony Forming Unit (CFU) and spore germination %, a sterile tap water was heated to 30, 50 and 70±5°C using a hot plate. A half ml-volume of hot water was transferred into one ml-in-volume test tubes (3 replicates per a treatment) and inoculated with a drop of fungal suspension made by washing the mold culture plate for each of the isolated mold fungi (Table 1) with a sterile tap water and set at a concentration of about 30000 spores per ml. Then, the test tubes were set at the same temperature for 2 minutes. One drop of water containing mold spores was taken from each test tube and added on a slide and spore germination % was then determined by counting the number of germinated spores. A 0.25 ml of each test tube was transferred into potato dextrose agar medium-containing Petri dish (3 plates/ a treatment). All culture dishes were then incubated at 25±2°C in darkness in a growth chamber for one week. After that, the number of emerging fungal colonies was counted per plate and the CFU/ml was determined per a plate and the average of CFU/ml for each treatment was calculated.

2.4. Mold-Olive Oil Interactions

A fresh virgin olive oil (10ml-volume per a 15ml glass test tube) was inoculated with a loopfull of each mold (Table 1) plate culture (3 replicates per treatment). All mold-inoculated oil test tubes were incubated at 25±2°C in darkness in a growth chamber for about three months. Percentage of mold colonization (in terms of mycelial growth and sporulation) of the oil was estimated; oil Peroxide Value (PV) and the percentages of Free Fatty Acids (FFA%) were measured using standard methods (IUPAC, 1979; Wong, 1989)

3. Results and Discussion

Table 1 shows that seven species of mold fungi were isolated from olive fruits infested with olive fruit fly; Alternaria solani (causes brown rot), Aspergillus niger (black mold), Cladosporium herbarum (sooty mold), Fusarium solani (fruit rot), P. digitatum (green mold), P. italicum (blue mold) and Rhizopus stolonifer (causes soft rot) with a sample frequency ranging between 6.7-33.3%. Among them, Penicillium digitatum was the most frequent mold species isolated from the fruit samples (Table 1).

* Over 200 rotted fruits with apparent mycelial growths were collected during November 2014.

At 50°C hot water treatment, there was a significant reduction in CFU/ml and in the spore germination % of the mold fungi except for P. digitatum and P. italicum where no significant reduction in the spore germination % at 50°C was recorded with 30°C (Table 2). At the highest hot temperature of water (70°C), all fungi showed remarkably lower CFU/ml and spore germination % than those at 30°C except P. digitatum and P. italicum that gave more than 50% spore germination at 70°C (Table 2).

All mold fungi were able to colonize olive oil (Table 3) and the range was from 5.7-36.2%. Mold colonization % of olive oil was significantly the highest for Rhizopus stolonifer while the lowest value was for Aspergillus niger.

Peroxide Value (PV) was significantly lower in the olive oil treated with Alternaria solani and Rhizopus stolonifer than that in the oil treated with the other fungi or in non-treated oil (Table 3).

The olive oil treated with P. digitatum and Rhizopus stolonifer had significantly higher FFA% than the oil treated with P. italicum. The increase or decrease caused by fungi in FFA% over the untreated control was not significant (Table 3).
Seven species of mold fungi were identified from olive fruits followed the infestation of olive fruit fly including Alternaria solani, Aspergillus niger, Cladosporium herbarum, Fusarium solani, P. digitatum, P. italicum and Rhizopus stolonifer with a sample frequency ranging between 6.7-33.3%. The low rate of colonization could be due to the occurrence of some natural inhibitors in the olive oil, such as polyphenols (Ruiz-Barba et al., 1990; Asehraou et al., 1992). Most of the isolated molds were vulnerable to hot water treatment at 50 and 70°C as indicated by the great reduction in their spore germination and colony forming unit. This is a valuable result since some olive mills usually use hot water to wash olive fruits, which has an additional value through its detrimental effect on spore germination and fungal growth. Physical, chemical and microbiological characteristics of olive oil can be affected by pre-milling storage time and the storage manner of the oil (El Haouhay et al., 2015). Generally, olives are very sensitive to physical damage and alterations caused by the presence and activity of microorganisms like molds, yeast and bacteria (Gutiérrez et al., 2009; Asehraou et al., 1992; El Haouhay et al., 2015). The seven isolated mold fungi were able to colonize olive oil through growth and spore production. Among them, Rhizopus stolonifer was the greatest colonizer and had obviously reduced PV of the oil and the same effect was also caused by Alternaria solani. When olive fruits were inoculated with some mold fungi, fungal infection had indirectly resulted in a significant increase in the extracted oil acidity and PV. However, there was no significant difference in the acidity and PV among different fungal isolates (Torbati et al., 2014).

Acidic pH even slight is most probably caused by the double action of the lipolytic microorganisms and/or lipases, which may release FFA. This can be supported by the high PV, which may indicate the level of the lipolysis (Asehraou et al., 1992). There was no considerable change in FFA three months after inoculating olive oil with different molds. Perhaps, a longer period of incubation may lead to significant changes in the oil FFA. Free fatty acids are related to the lipolytic action of some microorganisms, which are generally active inhibitors against most microorganisms (Asehraou et al., 1992). Storage of olive fruits and oil under uncontrolled environmental conditions had a drastic effect on the quality and shelf life of olive oil as indicated by the increase in its acidity and oxidation (Chliyeh et al., 2015; El Haouhay et al., 2015). Besides, a significant and important reduction of polyphenol contents and antioxidant capacity were detected in olive oil. The development of molds on olives is responsible for the poor nutritional quality of olives because molds can disturb the synthesis of fatty acids (Biasone et al., 2012; El Adlouni et al., 2000).

Insect pest infestation and bad storage conditions of olive fruits may enhance the activity of other microorganisms besides molds, e.g. Clostridium spp., Pseudomonas spp. and Enterobacter spp. (Angerosa et al., 1999). Olive oil produced under these adverse conditions not only leads to poor quality but could also put human health at risk. Mold growth on black table olives may be prevented by treating the fruits with sorbic acid, methyleugenol and spice essential oil where sorbic acid was the most efficient (Kivanç and Akgil, 1990).

Therefore, it is essential to have an effective management of the conservation of olives before and after

4. Discussion
harvest to avoid fungal mold infection and its adverse effects. Effective management of olive fruit fly would reduce its fruit infestation and secondary mold infections, which would improve olive oil yield and quality.
